SUMMARY: Three chronic prostatitis syndromes are recognised, chronic bacterial prostatitis (CBP), chronic nonbacterial prostatitis (CNBP), and prostatodynia. All may occur in men of military age, and may tax the patience of medical officers and patients whose capacity for full duty will be impaired. Diagnosis depends on identifying micro-organisms in CBP and white cells in CNBP in prostatic secretion (EPS) expressed by prostatic massage. In prostatodynia there are clinical features of prostatitis but no evidence of inflammation. Prostatic massage should be preceded by trans-rectal ultrasound which may show prostatitis and other pathology, and has simplified the investigation of these syndromes. Management includes a high fluid intake, regular bowels with a soft stool, regular prostatic drainage by ejaculation and limited alcohol intake. Antimicrobials are indicated for CBP and probably for CNBP, and need to be continued for at least three months in many cases. Other measures for treating CNBP are less well established. Prostatodynia is an ill defined syndrome which requires careful evaluation and patients may need psychiatric therapy.

Introduction

The chronic prostatitis syndromes are frequently regarded as ill defined, ill understood, difficult to diagnose, and difficult and tiresome to manage from the viewpoint of medical officer and patient (1). Over the last few years some of these difficulties have been clarified though problems remain. As these syndromes affect young men they will be found among servicemen and are worth reviewing.

Anatomy and pathology

The prostate is a tuboalveolar gland with a fibromuscular stroma and four zones within a fibrous capsule. In young men the peripheral zone is the largest and with the central zone comprises most of the volume of the gland; between them is a narrow transitional zone and there is a thin periurethral zone. The transitional zone is the site of benign hypertrophy in older men, while inflammation and cancer develop in the peripheral zone (2). Infection in the peripheral zone may be related to the right angle at which the ducts enter the urethra compared to the oblique angle of entry of the ducts draining the central zone (1). Simple histological examination of a cross section of the prostate shows inflammation to be multifocal (1).

Classification of the prostatitis syndromes

Chronic prostatitis refers to syndromes where the symptoms are subacute and persistent, compared to the dramatic features of acute prostatitis which is rare in western societies. Three common syndromes of chronic prostatitis have been described; chronic bacterial prostatitis (CBP), chronic non-bacterial prostatitis (CNBP), and prostatodynia. CBP is diagnosed when a urinary tract pathogen is isolated as described below, CNBP is diagnosed when there are excess polymorphonuclear leucocytes (PMNL) without an organism, and prostatodynia is the term used when there are symptoms of prostatitis without evidence of inflammation (1).

Aetiology

*Neisseria gonorrhoeae* is now rarely isolated from cases of chronic prostatitis in developed countries, but in the past was reported in prostatic abscesses (3,4). *Chlamydia trachomatis* is not established as a cause though some believe it to be important (5,6,7), and *Ureaplasma urealyticum* has also been implicated (8). *Trichomonas vaginalis* causes a few cases (9). Non specific urethritis may have a role in some men, but others have multiple attacks without developing prostatitis (10).

In CBP, *Escherichia coli* is the most commonly isolated bacterium, though other urinary pathogens also occur (11,12,13). There is rarely a focus of infection in the upper renal tract; more commonly the prostate is the source for recurrent bacteruria (13). Prostatic calculi have been implicated as foci of infection but calculi are common from middle age onwards. A recent study identified bacterial persistence in polysaccharide coated microcolonies within prostatic tissue; some of these patients had negative results to EPS cultures (14).

Though by definition no pathogens are isolated in CNBP, the inflammatory process may block the ducts draining the foci preventing organisms reaching the EPS. The surrounding inflammatory exudate may drain down nearby patent ducts producing excess PMNL in the EPS without any organisms (15). Intraprostatic reflux of urine has also been suggested following the identification of urinary constituents in prostatic calculi, and direct reflux of carbon particles into the prostatic ducts has been demonstrated in humans (16).

Prostatodynia may be related to emotional disturbance, psychiatric conditions especially depression, tension myalgia in the pelvic floor muscles, functional voiding...
problems, bladder neck dyssynergia, or possibly other conditions including prostatitis itself. Pain from prostatitis or other conditions innervated by S2, 3 and 4 may also lead to tension myalgia in the pelvic floor muscles causing or exacerbating pain (17,18,19,20).

Prevalence
The prevalence of these syndromes is unclear. In 1970 at the venereal disease clinic in the British Military Hospital Singapore, 36.8% of 95 men who had been treated three months previously for urethral gonorrhea and 13.6% of 66 men treated for non-gonococcal urethritis were diagnosed as having prostatitis. At the Royal Herbert Hospital, Woolwich, 16.7% of 36 men treated for gonococcal urethritis and 35.4% of 48 men treated for non-gonococcal urethritis were diagnosed as having prostatitis (21). In the UK and Holland civilian general practitioners diagnose 1-10 patients per year (22,23). In Germany at a urological department with an interest in these syndromes, 5-10% were CBP, 60-65% CNBP, and 30% prostatodynia (8). In the UK at a tertiary referral clinic for chronic prostatitis, 30% were CBP, 40% CNBP and 30% prostatodynia; ages ranged from 20 to 56 years and were similar in the three syndromes (10).

Clinical features
Symptoms are similar in all three syndromes and are listed in Table 1. Digital examination of the prostate is frequently unhelpful. Tenderness localised definitely to one area of the prostate is very suggestive of prostatitis, tenderness referred to the urethra or penile tip is suggestive, but generalised tenderness is difficult to interpret. Tenderness contraindicates prostatic massage (1,18). Diagnosis rests on investigations (1,18).

(1,18).

Investigations
Established methods comprise cytological and cultural examination of prostatic secretion (EPS) and of urine passed before and afterwards (24). If there is any suggestion of urethritis the patient should be referred to a genitourinary medicine clinic before prostatic massage.

The details of prostatic investigations and their interpretation are summarised in Tables 2 and 3. This method is often referred to as the Stamey technique after the senior author who first described it (24). Patients should be advised to hold their urine for two hours and avoid ejaculation for two days before investigation. No prostate penetrating antimicrobial (see below) should be taken before a week before investigation. Samples should be examined as soon as possible; this needs close collaboration with the laboratory. Simple microscopic estimations of white cells can be done in the clinic and counts can also be done on the spot using a Fuchs Rosenthal counting chamber (18). Ideally quantitative aerobic and anaerobic microbiological cultures should be done (25).

Where possible, before undertaking prostatic investigations a transrectal ultrasound scan (TRUS) of the prostate should be undertaken. TRUS may also indicate conditions which may be confused with or complicate prostatitis including prostatic cysts, abscesses and calculi, disease of the seminal vesicles, bladder neck dysfunction, benign prostatic hypertrophy and carcinoma. TRUS may also suggest the rare granulomatous, eosinophilic and tuberculous forms of prostatitis. A normal scan may be found with an abnormal EPS. A major role for TRUS is to guide a needle for aspiration or biopsy, though the multifocal nature of
prostatitis does not usually lend itself to needle aspiration unless complicated by a cyst or abscess (10).

**Diagnosis**

The diagnosis of CBP is based on finding a pure growth of a urinary pathogen in the EPS and post prostatic massage urine or voided bladder urine 3 (VB3) in the absence of simple bacteruria. In CNBP a white cell count of 1000 PMNL/cu mm in the EPS is regarded as diagnostic; if simple microscopy of the EPS is undertaken at least 10 PMNL/ X40 microscope field are required. Clumping of PMNL also indicates prostatitis. If EPS is not obtained, increased PMNL in the VB3 is associated with prostatitis. A raised EPS pH (>8.0) is corroborative, but prostatitis may be present with a lower pH. Prostatodynia is diagnosed when there are clinical features suggesting prostatitis but no pathogen or excess PMNL can be demonstrated (10).

**Differential diagnosis**

The chronic prostatitis syndromes may mimic or coexist with a variety of conditions within and outwith the urinary tract. Carcinoma of the prostate and elsewhere in the lower genital tract is most important and is usually found in older men. Other prostatic pathology including cysts, abscesses, calculi and benign prostatic hypertrophy will be shown by TRUS which may also show disease of the seminal vesicles. Bladder diverticula will be recognised on upper renal tract imaging. Warts or extra folds of mucosa in the upper urethra may disturb urine flow and cause prostatitis; these are extremely rare.

These conditions will be excluded by undertaking the investigations outlined for the diagnosis of prostatitis and those listed in Table 4. Urine cytology, serum prostate specific antigen (PSA) and EMUs should be requested for all patients. PSA may be elevated in prostatitis and carcinoma. Any person with obstructive symptoms should have a flow rate. Renal tract imaging is less important for younger men with the advent of TRUS. However men over 45 years, any man with haematuria or any feature suggesting carcinoma should have renal tract imaging and referral for endoscopy before prostatic massage or treatment for prostatitis.

Conditions outside the renal tract must also be considered. Diverticulitis can cause irritative voiding symptoms and pain suggesting prostatitis but usually presents in older men. Inguinal region pain may be due to a hernia or ligament disease, while pain may also be referred from the spine. Genital herpes may also cause confusing pain before lesions appear.

**Management**

In all the prostatitis syndromes general measures including explanation, reassurance, counselling and psychological support are important. In addition a high fluid intake, such as 3 litres daily, regular bowel habit with a soft stool, and regular prostatic drainage by ejaculation are all beneficial (15,26). Possibly regular overall habits help. Patients should not be set unrealistic targets which lead to anxiety. The natural history of chronic prostatitis is gradual improvement with intermittent exacerbation of symptoms; this must be explained. Sometimes these exacerbations have an explanation such as reduced fluid intake; others are inexplicable.

Antimicrobials which theoretically penetrate well into the prostate should be lipid soluble, low protein binding, and with an appropriate dissociation constant (high pKa) (27). These include trimethoprim, minocycline, doxycycline, erythromycin, azithromycin, and the quinolones of which ciprofloxacin has been the most studied (27,28). Experience suggests that full doses are required for three or more months. Progress can be monitored objectively by repeating the EPS examination. In CBP a pathogen is identified and antimicrobial sensitivities obtained. Ciprofloxacin 250-500mg or trimethoprim 200mg twice daily are usually effective (27,29).

In CNBP there is a rationale for giving antimicrobials following the hypothesis of blocked ducts. Antimicrobials may be selected on the basis of the history; if this suggests bacteruria then a quinolone or trimethoprim may be chosen; if there has been recurrent urethritis then doxycycline, minocycline, erythromycin or azithromycin may be given. One controlled study of erythromycin suggested benefit compared to placebo (30). In another non-random study trimethoprim and minocycline gave greater reduction in EPS PMNL counts than cotrimoxazole or diazepam (31). In two small randomised double blind trials of minocycline versus diazepam and doxycycline versus placebo, the antimicrobials gave better results (32,33).

Other suggestions include anti-inflammatories though little evidence has been found to support their use and personal clinical experience has been disappointing (15,34). Pollen extract has been described as beneficial; it may be anti-inflammatory through prostaglandin synthesis inhibition and by anti-adrenergic activity (35,36). Several reports have described improvement following transrectal or transurethral microwave hyperthermia (37,38).

Acute exacerbations of symptoms may respond to a short course of propantheline, or prednisolone though only one reference has been traced for this (34).

In prostatodynia, emotional and psychiatric conditions may need specialist care (19). Tension myalgia improves when the patient relaxes; for example some patients get
relief from pain when they relax in the evening or when on holiday. Alcohol should be avoided as some patients report exacerbation of pain almost as soon as they start a alcoholic drink; reasons for this are obscure. Large amounts of alcohol are contraindicated as they may increase voiding problems and cause subsequent dehydration. Functional voiding problems and bladder neck dyssynergia may be recognised during sphincter. 

Comment

The classification repeated here has been accepted for some years; the concept of prostateodynia is somewhat vague but appears to be retained for the clinical similarity with CBP and CNBP (1). If prostateodynia is thought to be the diagnosis, organic causes for the symptoms must be considered before settling for a psychological aetiology.

TRUS has greatly simplified investigation of these syndromes and many patients who would previously have been subjected to IVU and endoscopy are now spared these invasive investigations. Prostatic massage to obtain EPS is a tedious procedure and it has been suggested that a mid-stream urine before prostatic massage or voided bladder urine 2 (VB2) and VB3 samples may be sufficient; without EPS CBP may be missed (10). If EPS cannot be obtained then VB3 should be sent for investigation, but repeat prostatic massage should be considered.

Unlike some published data, clinical experience indicates that prolonged treatment is required for most patients. Intra-prostatic injection of antimicrobials has been described but reports of response have been variable (40). The logic of introducing high concentrations of antimicrobials into one area of multifocal inflammation are unclear; at least the process of needling the prostate can be done more safely with TRUS control. More research is clearly needed into aetiology and management. Until new answers are found these chronic syndromes will tax the patience of medical officers and their patients whose capacity for full duty will be impaired.
